MODAL

Mathematical Optimization and Data Analysis Laboratories

- ▶ How to measure numerical stability of a MIP solver?
- ▶ How does the stability evolve during optimization?
- ▶ Can we keep numerical stability under control?
- ▶ What is the influence of cutting planes and branching?

1. Introduction
2. Computing the Condition Number
3. Condition Numbers in the Root
4. Condition Numbers in the Tree
5. Conclusion and Outlook

1. Introduction
2. Computing the Condition Number
3. Condition Numbers in the Root
4. Condition Numbers in the Tree
5. Conclusion and Outlook

How does the output of an algorithm change after small changes to its input?

- ▶ How do numerical errors accumulate?
- ▶ Up to which precision can the result be trusted?

1. solve LP relaxation
2. add cutting planes
 - ▶ re-solve LP relaxation including new inequalities
3. branch on a fractional variable
 - ▶ repeat process on both resulting sub-problems

cutting:

- ▶ should be preferred to branching
- ▶ no additional sub-problems, only one re-optimization
- ▶ often struggles from numerical difficulties ("parallel" cuts)
- ▶ cut quality degrades over time (tailing off effect)

branching:

- ▶ branching disjunctions represent "best cuts possible"
- ▶ guaranteed to be orthogonal to each other
- ▶ only have one nonzero component (very sparse)
- ▶ **drawback:** effectively doubles the problem

- ▶ We use the condition number of the **optimal basis of the LP relaxation**
- ▶ This basis is used for generating Gomory cutting planes
- ▶ This basis determines how accurate the LP solution is ($x_B = A_B^{-1}b$)
- ▶ Excellent and detailed reference for condition and numerical stability:

P. Bürgisser and F. Cucker

Condition - The Geometry of Numerical Algorithms

Vol. 349. Grundlehren der math. Wissenschaften. Springer, 2013.

1. Introduction
2. Computing the Condition Number
3. Condition Numbers in the Root
4. Condition Numbers in the Tree
5. Conclusion and Outlook

- ▶ Always consider the condition number wrt $\|\cdot\|_2$:

$$\kappa := \|A\|_2 \cdot \|A^{-1}\|_2$$

$$\text{where } \|A\|_2 := \max_{\|x\|_2=1} \|Ax\|_2$$

- ▶ Computing κ can be expensive and is as stable as κ itself
- ▶ Accuracy is not too important
- ▶ Sufficient to inspect $\log_{10}(\kappa)$

Power method:

- ▶ perform subsequent multiplications with A and A^T until convergence to largest singular value σ_1 of A
- ▶ repeat with the inverse A^{-1} to get smallest singular value σ_m
- ▶ $\kappa = \sigma_1/\sigma_m$

-
- ▶ Provides a precise value, but requires expensive computation
 - ▶ Faster approximations to estimate the condition number are available

Software and tools:

- ▶ [SCIP Optimization Suite](http://scip.zib.de)
<http://scip.zib.de>
- ▶ [GrUMPy - Graphics for Understanding Mathematical Programming in Python](http://github.com/coin-or/GrUMPy)
<http://github.com/coin-or/GrUMPy>

Test set:

- ▶ combined benchmark sets of all three MIPLIBs (2003, 3, and 2010)

Settings:

- ▶ aggressive Gomory separator: generate cuts at all nodes and add more cuts (default SCIP only separates cutting planes at the root node)
- ▶ deactivate other cut generators
- ▶ time limit: 1h
- ▶ node limit: 10 000

1. Introduction
2. Computing the Condition Number
3. Condition Numbers in the Root
4. Condition Numbers in the Tree
5. Conclusion and Outlook

- ▶ Dual simplex starting with slack basis ($A_B = I$):
 - ▶ κ increases quickly from the initial 1.0
 - ▶ almost monotone increase until characteristic κ is reached
 - ▶ adding cuts often increases κ significantly
 - ▶ tailing off effect can be seen

- ▶ Condition number increase due to cuts in the root node
- ▶ Mean and final difference over cutting phase

1. Introduction
2. Computing the Condition Number
3. Condition Numbers in the Root
4. Condition Numbers in the Tree
5. Conclusion and Outlook

- ▶ Changes in condition number wrt branching and cutting
- ▶ **Branching:**
Compare parent node after cutting and child node before cutting
- ▶ **Cutting:**
Compare before and after cutting at each node
- ▶ Branching does not significantly increase or decrease κ
- ▶ Cutting leads to an increased κ over all nodes

Different approach:

- ▶ Compare a run using cutting with a pure branch-and-bound optimization

Different approach:

- ▶ Compare a run using cutting with a pure branch-and-bound optimization

Different approach:

- ▶ Compare a run using cutting with a pure branch-and-bound optimization

Different approach:

- ▶ Compare a run using cutting with a pure branch-and-bound optimization

- ▶ regression slopes for all instances
- ▶ tree depth of at least 5
- ▶ no significant degradation or stabilization through branching
- ▶ clearly positive slope when adding cuts

▶ no satisfactory feature for "good" cuts found yet

1. Introduction
2. Computing the Condition Number
3. Condition Numbers in the Root
4. Condition Numbers in the Tree
5. Conclusion and Outlook

- ▶ Intuitive assumptions are not always correct
- ▶ Numerical analysis is often more demanding than expected
- ▶ More evaluations and experiments are necessary
- ▶ Try different stability measures / different condition numbers
- ▶ Test other solvers (both LP and MIP)
- ▶ Find better cut selection and filtering
- ▶ Gain a more holistic approach to algorithmic control
